Abstract

For two decades it was believed that chiral symmetries cannot be realized in lattice field theory but this has changed now. Highlights of these new developments will be presented with emphasis on the mathematical structure of the so called “overlap”.

1 Introduction

Up to energies E , tested in present day’s most powerful accelerators, one finds that Nature can be accurately described by a “standard model”, a chiral gauge theory with a small non-vanishing short-distance cutoff $\frac{1}{\Lambda}$ of unknown form but known magnitude. Accurate predictions are possible, despite ignorance about short distances, because the theory is renormalizable. To accuracy $\frac{E}{\Lambda} \approx 10^{-12}$ the influence of the short distance structure can be entirely absorbed in a few measurable parameters the chiral gauge theory depends on. Future experiments will increase E , and possibly change the standard model. Very likely, the model will just evolve into another chiral gauge theory, maybe supersymmetric.

Renormalizability is rigorously established order by order in “perturbation theory” (a certain asymptotic expansions of the theory), but is more difficult to prove for the theory as a whole. Mainly because the theory is chiral, renormalizability outside perturbation theory is problematic.

Although not established with full mathematical rigor, the accepted view is that any theory is renormalizable outside perturbation theory if one can replace its true short distance structure by a discretization obeying certain general restrictions. When the discretization preserves enough of the symmetries one extracts physical information by going to a “continuum limit” where short distance details

^aInvited talk at “Trends in Mathematical Physics”, Oct. 14-17, University of Tennessee, Knoxville, USA.

of the construction become irrelevant. It is relatively easy to discretize “vectorial” gauge theories, but chiral gauge theories pose new difficulties. There, perturbative renormalizability hinges on a delicate cancelation (of “anomalies”) and it is difficult to incorporate this cancelation at a fundamental level in lattice formulations. Until quite recently, because of several “no go theorems”, it was suspected by some that chiral gauge theories may not be renormalizable outside perturbation theory. This belief has lost many subscribers by now.

A less severe, but related problem occurs even in the context of vectorial gauge theories where almost exact global chiral symmetries (i.e. “not gauged”) are known to hold. Traditional lattice regularizations require an unnatural and cumbersome fine tuning to achieve global chiral symmetries in the continuum limit. Until recently it was thought that one cannot preserve exact global chiral symmetries before the continuum limit is taken.

One does not need to study the renormalizability of the complete gauge-matter system in order to deal with the problem of chirality. Unlike in renormalization theory, the specific issues one needs to resolve when quantizing chiral fermions are almost independent of the (even) dimensionality of the model. The problem of quantizing chiral fermions in a fixed gauge field background can be formulated in any even Euclidean dimension.

Renormalizability of the theory as a whole is an issue that can be separated from the problem of chirality. The quantization of gauge-matter systems can be split into two steps: In the first only the fermions are quantized, while the gauge field background is kept fixed. In the second, also the gauge fields are quantized. We only need to worry about the first step. This step, in isolation, has trivial renormalization - and can be analyzed in any (even) dimension. The second step typically requires Euclidean dimension less than or equal to four.

If one so chooses one can deal with the quantization of the entire system as a whole. But, in my opinion, this would be a bad idea. A crucial simplification is afforded by fermionic matter entering the action only bilinearly and this simplification is only exploited fully in the two step approach.

2 The lattice and the overlap

Our mathematical problem can be described as follows. Start from a $2d$ dimensional compact Riemannian manifold M . It is the base space of a principal fiber bundle with structure group $\mathcal{G}$. We also have an associated spin bundle and the Dirac operator D acting on its sections. The spin bundle can be decomposed into its chiral components and there are two Weyl ($W_{L,R}$) operators connecting corresponding sections. We shall simplify our discussion to flat Riemannian manifolds with the topology of a $2d$ -dimensional torus, T^{2d} . Also, to be specific, we shall pick $\mathcal{G} = SU(n)$. We replace the torus by a hypercubic finite lattice with sites x . Connections on the fiber bundle are replaced by discrete collections of elementary parallel transporters $U(x, y)$. Parallel transport along a sequence of arcs (x, y) in the graph associated with the lattice is implemented by an ordered product of $U(x, y)$ along the path. The individual parallel transporters are $SU(n)$ matrices. A collection of “link variables” U makes up the “gauge background”. At each site of the lattice we can perform an $SU(n)$ rotation on the local frame, inducing a “gauge transformation” on the connection. A collection of connections related by all possible gauge transformations constitutes a “gauge orbit”. In the continuum limit, physical degrees of freedom are associated only with orbits, not with individual connections.

In the continuum, physical results require an integration over all orbits with certain weight functions. The integrals are written as integrals over connections but the integrands are picked gauge invariant, i.e. dependent only on the orbit. This integration is carried out as part of step two in the construction program. Step one is required to provide two kinds of quantities, both determined by the gauge background: The first one is a function and plays the role of the determinant of the Weyl operator. The determinant is expected to be gauge invariant. The other class of quantities contains the matrix elements of the inverse of the Weyl operator evaluated in a standard basis. These are the “fermionic Green’s function” or “propagators”. The Green’s functions must transform by conjugation under gauge transformations. One cannot pick arbitrarily independent definitions for the determinant and the fermion Green’s functions: Variations of the determinant under small deformations of the gauge background have to obey natural expressions in terms of the fermion Green’s functions.

On the lattice we would expect to replace the continuum operators by finite matrices with a standard definition of finite dimensional inner products replacing the continuum inner product in the Hilbert space of sections. However, since the Weyl operators can have a nonzero analytical index which depends on the gauge field, one cannot decide in advance on the shape of the matrices. This observation, although quite trivial, is relatively new and was crucial to the progress I am reporting on.

The disconnected space of connections we are familiar with in the continuum is replaced by a product of $SU(n)$ group manifolds, one for each link. Thus, the “parameter space” of our matrices is now connected and cannot admit a smooth definition of “shape” except when it is constant. This difficulty faced by lattice regularizations is well understood since the work of Phillips and Stone on “lattice topology”; one needs to excise from the set of all lattice gauge backgrounds some subset, preferably, but not necessarily, of zero measure. This leaves behind a more complicated parameter space, cut up in disconnected pieces. On each piece the shape of the matrix representing the Weyl operators is fixed. The shape is defined by an integer determining the difference between the number of rows and columns, $2k$. The sum of the two, $2K$ ($K \geq |k|$), can and is kept fixed, determined solely by the lattice and n . Each matrix is paired with a complementary one, with opposite sign of k . The complementary matrix is associated with Weyl fermions in the conjugate representation, or equivalently, with fermions of opposite handedness. The two matrices can be assembled together into a $2K \times 2K$ matrix (each side of this matrix has a length equal to the sum of the numbers of rows and of columns of either Weyl matrix) representing Dirac fermions. The bigger matrix has a fixed shape, independently of the gauge background. The main reason why vectorial gauge theories are so much easier to define is that the Dirac operator can be replaced by a matrix of fixed shape. However, to preserve exact masslessness one needs to preserve exact decoupling between left and right components. Since the two Weyl blocks cannot have a fixed shape any discretization preserving exact masslessness of Dirac fermions on the lattice has a Dirac matrix which is not analytic in the link parallel transporters.^b

^bThis has some interesting consequences: It goes without saying that the Dirac matrix must change by conjugation under gauge transformations. In turn, this means that the Dirac matrix connects two distinct sites by a sum over path ordered products of elementary link matrices. All this goes through also for a structure group given by $U(1)$. In this case, one can pick as an example all parallel transporters in a fixed direction as equal to each other, given by e^{ip_μ} , $\mu = 1, 2, \dots, 2d$. Our discussion implies that the resulting reduced Dirac matrix cannot be analytic on the torus spanned by the p_μ ’s. This implies that the Dirac matrix cannot be sparse in site space.

The “overlap” provides a construction of matrices representing Weyl operators. One starts with the easier problem of defining on the lattice a certain massive Dirac operator. One picks an appropriate Hermitian operator H_W which transforms covariantly under lattice gauge transformations and represents massive Dirac fermions. There are no difficulties because chiral symmetries are absent for massive fermions. There is a large amount of latitude in choosing the structure of H_W : the single requirement is that H_W be a lattice approximation to a massive Dirac operator with a *negative* and large mass term.^c One excludes all lattice gauge field backgrounds for which H_W has a nonzero kernel. (On the lattice, if one chose a negative mass term, this kernel will end up being non-empty for many backgrounds.) This exclusion is gauge invariant; in other words gauge orbits are excluded in their entirety. Over the remaining space of gauge backgrounds one unambiguously splits the finite vector space $\mathcal{V}$, on which H_W acts, into $\mathcal{V}_+ \oplus \mathcal{V}_-$ where $\mathcal{V}_\pm$ are the images

of $\mathcal{V}$ under $\frac{1 \pm \varepsilon(H_W)}{2}$. $\varepsilon(x)$ is the sign function. $\mathcal{V}$ also has a canonical split into $\mathcal{V}'_+ \oplus \mathcal{V}'_-$ induced by $\gamma_{2d+1} \equiv \epsilon'$. The chirality operator ϵ' also splits the spin bundle in the continuous case. There, it splits the Dirac operator into Weyl operators. Here, the lattice Weyl operators are represented by “overlap” matrices between the corresponding subspaces $\mathcal{V}'_+$ and $\mathcal{V}_+$ for one handedness and $\mathcal{V}'_-$ and $\mathcal{V}_-$ for the other. The massless Dirac operator is realized on the lattice as a combination of the two, and is given by $D_o = \frac{1 + \gamma_{2d+1}\varepsilon(H_W)}{2}$. Alternatively, one deals with its hermitian version, $H_o = \gamma_{2d+1}D_o = \frac{\gamma_{2d+1} + \varepsilon(H_W)}{2} \equiv \frac{\epsilon' + \epsilon}{2}$.

3 Vectorial gauge theory and topology

The continuum massless Dirac operator maps elements of $\mathcal{V}'_\pm$ (left/right components) into elements of $\mathcal{V}'_\mp$. For this reason, if there are several copies (flavors) of massless Dirac operators their left and right components can be complex-rotated into each other independently without changing the determinants. A flavor independent mass term would prohibit independent rotations, and only a vectorial symmetry, with both rotations equal to each other, would be allowed. The technical difference between the massive and the massless Dirac operators is that the latter anticommutes with ϵ' .

Since ϵ and ϵ' are hermitian and square to one, the operator $V = \epsilon'\epsilon$ is unitary and obeys $\epsilon'V\epsilon' = V^\dagger$. Actually, if we only know that we have a unitary operator V with the above property, we can define ϵ so that it be hermitian and square to one. Unlike the continuum Dirac operator, the lattice overlap Dirac operator $D_o \equiv \frac{1+V}{2}$, does not anticommute with ϵ' .

All the important consequences of chiral symmetry are expressed in terms of identities between products of matrix elements of the inverses of the Dirac operator (propagators). Now, $D_o^{-1} = \frac{2}{1+V} = \frac{1-V}{1+V} + 1$. The first term, $\frac{1-V}{1+V}$, is easily seen to

anticommute with ϵ' . Thus, the single violations of the chiral identities will occur for identities involving diagonal elements of the inverses. There are many chiral identities, and most do not involve diagonal elements of the inverses. Actually, the violations are immaterial for the continuum limit; in ordinary field theory one always

^cOn the lattice the actual distinction between a positive and negative mass is that the massive lattice Dirac operator with positive mass can be smoothly deformed to infinite positive mass without ever becoming singular. The negative mass operator does not admit such deformations.

expects singularities to arise when operators are multiplied at the same point.^d In the process of constructing the algebra of local operators in the continuum these singularities need to be redefined anyhow. Thus, for anything that really matters, chiral symmetry is preserved even with D_o .

That chiral symmetry would work on the lattice by allowing some local violations in the propagators was observed a long time ago by Ginsparg and Wilson who formalized the requirement in a certain relation; however they did not produce an explicit example for an acceptable lattice Dirac operator satisfying their relation in arbitrary gauge backgrounds. They showed that a lattice action will essentially have exact global chiral symmetry if the fermion matrix, D_{GW} , obeyed the requirements $\{\gamma_5, D_{GW}^{-1} - R\} = 0$ ($\{\dots\}$ denotes the anticommutator), with

$R = R^\dagger$, $[\gamma_5, R] = 0$ and $\gamma_5 D_{GW}$ hermitian, while R is a “local” operator, strongly

diagonally dominated in site space. Defining $D_c^{-1} = D_{GW}^{-1} - R$ and the unitary

matrix $V = \frac{1-D_c}{1+D_c}$ we find that the most general solution of the Ginsparg-Wilson

requirements is $D_{GW}^{-1} = D_o^{-1} + R - 1$, where D_o is an overlap Dirac operator. Apparently, there is no advantage in picking an R different from the unit matrix, and one often restricts D_{GW} to D_o . The crux of the matter is to find a unitary matrix V for which $\epsilon = \epsilon' V$ is hermitian such that the associated D_o be a faithful approximation to the massless continuum Dirac operator. Equivalently, one can look for a

hermitian ϵ which squares to unity so that $\frac{1+\epsilon'\epsilon}{2}$ is an acceptable approximation to the massless continuum Dirac operator.

When the gauge background is a connection on a nontrivial bundle over the torus, the continuum Dirac operator has exact zero modes because its Weyl components have a nontrivial analytic index. On the lattice the associated topological integer is $\frac{1}{2} \text{tr} \epsilon$. One can prove that the associated zero modes exist as follows. Consider two orthonormal bases, $\{\psi'_j | \epsilon' \psi'_j = \epsilon'_j \psi'_j, j = 1, 2, \dots, 2K\}$ and

$\{\psi_j | \epsilon \psi_j = \epsilon_j \psi_j, j = 1, 2, \dots, 2K\}$. Obviously, the ψ_j can be chosen as also eigenvec-

tors of H_W . Exactly K of the ϵ'_j 's are unity. One has $(\psi'_j, H_o \psi_i) = (\psi'_j, \psi_i) \frac{\epsilon'_j + \epsilon_i}{2}$ so

the rank of $D_o (= \epsilon' H_W)$ is generically equal to $2K - |\text{tr} \epsilon|$, as expected. For generic backgrounds the rank will not change under small but arbitrary deformations of the connection.

It is easy to write down operators ϵ, V and their associated D_o , which simply do not represent massless fermions and also are insensitive to topology, but nevertheless obey the Ginsparg-Wilson relation.

4 Propagators, the determinant bundle and anomalies

With the help of the operators ϵ and ϵ' one can decompose the total space $\mathcal{V}$ into a direct sum of orthogonal subspaces in two ways: $\mathcal{V} = \mathcal{V}'_+ \oplus \mathcal{V}'_-$ with $\epsilon' = \pm 1$ on $\mathcal{V}'_\pm$ or $\mathcal{V} = \mathcal{V}_+ \oplus \mathcal{V}_-$ with $\epsilon = \pm 1$ on $\mathcal{V}_\pm$. The second decomposition is well defined only for backgrounds where H_W is invertible. Let the associated orthogonal projectors be $P'_\pm, P_\pm$. Let us think about the projectors as maps from $\mathcal{V}$ to the respective subspaces. So, if bases are chosen, the projectors $P'_\pm$ would be represented by

^dThe local operators are more accurately described as operator valued distributions.

rectangular matrices with $2K$ columns and $K \pm k$ rows while the projectors $P_{\pm}$ would be represented by $K \times 2K$ matrices. The Weyl operator $W^L : \mathcal{V}'_+ \rightarrow \mathcal{V}_+$ is given by $P_+ P'_+{}^\dagger$ and $W^R : \mathcal{V}'_- \rightarrow \mathcal{V}_-$ is given by $P_- P'_-{}^\dagger$. Their “inverses” (propagators) are extended to $\mathcal{V}$ as $G^L = P'_+{}^\dagger \frac{1}{P_+ P'_+{}^\dagger} P_+$ and $G^R = P'_-{}^\dagger \frac{1}{P_- P'_-{}^\dagger} P_-$.

These propagators have ranks $K \pm k$.

The subspaces $\mathcal{V}_{\pm}$ are defined in a gauge invariant way: the subspaces do not change along gauge orbits, so can be viewed as defined over the space of allowed gauge connections modded out by gauge transformations. Intuitively, W^L measures a “distance” between the spaces $\mathcal{V}'_+$ and $\mathcal{V}_+$. If W^L is a unit matrix (up to phases) the spaces coincide.

The “determinant” has to be $\det W^L$. It can be nonzero only for zero topology, since otherwise W^L isn’t square. Although the map W^L is completely determined by the subspaces $\mathcal{V}'_+$ and $\mathcal{V}_+$ (which are defined in a gauge invariant way), since it connects two different spaces, there is no natural numerical determinant one can associate to it. This mirrors the situation in continuum. What we really end up with is a definition of a line bundle over the space of admissible gauge orbits, not a function. The problematic part is a determinant bundle given by the collection of all spaces $\mathcal{V}_+^\wedge = \mathcal{V}_+ \wedge \mathcal{V}_+ \wedge \dots \mathcal{V}_+$, where the number of factors is the dimension of $\mathcal{V}_+$. In physics, a choice of basis in a $\mathcal{V}_+^\wedge$ is a “ground state” in a “second quantized fermionic system” with strictly bilinear interactions given by H_W . It is crucial that W^L is constructed from H_W which is C^∞ in the gauge background, even before any gauge configurations have been excised. We only have a line bundle, so the phase of the complex number $\det W^L$ is still undefined. The bundle base space is the collection of gauge orbits, so gauge invariance is automatic but there may be no smooth sections. In other words, while $|\det W^L| = |\det(P_+ P'_+)|$ is gauge invariant,

it is not yet sure that $\det W^L$ can also be made gauge invariant smoothly in the background gauge orbits. This smoothness is necessary for meaningful quantization.

To make progress we need to go back a step and work over the space of connections rather than gauge orbits. This space is contractible in each topological sector. We have the same fibers as before. Now we pick a section. The section naturally produces a one form over base space. This one form can be viewed as a connection in a $U(1)$ bundle. In Physics it is known as Berry’s connection. In our case Berry’s connection corresponds to a known function of the gauge background in the continuum, namely the difference between the “covariant anomaly” and the “consistent anomaly”. When this difference is nonzero, any definition of a gauge invariant chiral determinant becomes untenable in the continuum. On the lattice it is suspected that, if Berry’s connection turned out to vanish, the section it came from could be made gauge invariant. Then we could take this section over the space of gauge orbits and we would be done. If Berry’s connection vanished, Berry’s curvature, an exact two-form, would also vanish. Berry’s curvature is however always gauge invariant, it is a property of the collection of the vector spaces themselves, independent of basis choices. Therefore, Berry’s curvature two-form can be taken over the space of gauge orbits, no matter what section we started with. Generically, it does not vanish. Berry’s curvature is entirely determined by H_W . Therefore, the first question to ask is whether one can deform H_W in such a way that Berry’s curvature vanishes. ^e Here the latitude we allowed ourselves in the choice of H_W

^eThe two form is unchanged under $H_W \rightarrow g(H_W)$ where the real continuous function g satisfies

gets exploited. By checking some examples it was found that there are cases where no small deformation of H_W can make Berry's curvature vanish. The obstruction shows up as follows: One picks a special two dimensional, non-contractible compact submanifold in the space of gauge orbits and shows that the integral of Berry's two form over it gives a nonzero integer. These integers turn out to govern the continuum anomalies of the chiral fermions one tries to discretize. This might be the deepest geometrical feature of the overlap construction. For the first time in lattice field theory one sees a purely geometrical role played by anomalies, directly on finite lattices !

On the basis of these findings I conjecture that if continuum anomalies cancel it is possible to deform H_W in such a way that the associated Berry curvature vanishes. I also conjecture that if Berry's curvature vanishes there is a smooth section through the determinant bundle over the space of gauge orbits. Assuming that these conjectures are correct, there still remains the question whether an explicit expression for H_W and for the smooth sections can be written down. It seems that even if constructive proofs are found the explicit formulae would be too complicated to be usable in numerical work. Nevertheless, I don't think numerical work is condemned to be impracticable, so long as the main goal is limited to approaching the correct continuum limit.

I believe that, as far as Physics goes, an explicit construction is not really necessary. There are good reasons to believe that even if one integrated a weight that was not exactly gauge invariant over all connections the result would still have the correct continuum limit. The integration along the orbit can be viewed as an averaging over the compact group of gauge transformations. The integration over connections can be split into two stages, where in the first one averages over gauge orbits, producing a gauge invariant weight to be further integrated over orbits. Even if one used an H_W for which Berry's curvature did not vanish and a section in the bundle over connections that was not gauge invariant the net result would have the same continuum limit as one would get with a carefully chosen H_W for which Berry's curvature does vanish. It suffices that the actual H_W is sufficiently close to the finely adjusted one. The basis of this belief is a certain generalized universality first proposed by Förster, Nielsen and Ninomiya on the basis of investigating some toy models. Indeed, it would be unnatural if the correct continuum limit depended on whether one picks a complicated exact H_W or just an approximation.

An interesting degenerate case holds for $SU(2)$, where a related issue, first pointed out by Witten, arises for Weyl fermions in pseudoreal representations. All the spaces we dealt with can be taken over the reals, and one ends up with a $Z(2)$ determinant bundle rather than a $U(1)$ one. In this case one has no Berry curvature, just Berry holonomies. Explicit examples with nontrivial irremovable Berry holonomy were constructed when anomalies are known to occur in the continuum. The nontrivial holonomy was found by computer, using a well known relation between degeneracies in H_W and Berry holonomy.

5 Numerical Methods

For vectorial theories any reasonable H_W would work. But, one needs to make it as sparse as possible if one wants a practical procedure. This is of direct interest in QCD, a vectorial gauge theory describing strong interactions.

$\varepsilon(g(x)) = \varepsilon(x)$. It might be convenient to search for the new H_W in the form $g(H_W) + \delta$, where δ is a small deformation.

In Nature, the “strong interactions” become strong only at relatively low energies while all unknown physics resides at high energies. One might think that one should not be in the way of the other. But, because of their strength, the strong interactions mask numerically almost any other property of strongly interacting particles. It is important to be able to calculate these “masking factors” in order to separate out potentially interesting new Physics from the measured quantities. There is only one method based on first principles to do the needed calculations. This is the specialty of the subfield of numerical lattice QCD. As I already mentioned, in Nature, there are almost exact global chiral symmetries and one needs to reproduce them one way or another on the lattice. Recent developments indicate that this might be now doable much more elegantly than before.

In practice, one uses almost exclusively Krylov space methods, since the matrices H_W are of the order of $10^6 \times 10^6$ and more. Only their sparseness saves the day and the numerical methods one can at all consider must use only matrix acting on vector operations.

At the moment the methods of choice use some approximant for the sign function $\varepsilon(x)$. One requires that numerical work proceed with relative efficiency, while, at the same time, the approximation be of reasonable quality. Almost all methods essentially use a rational polynomial approximant. It is unclear at present against what criteria should one optimize the approximant $\varepsilon_n(x)$ to the sign function. A nice coincidence is that in the area of control theory, applied mathematicians have been faced with the need to deal with the $\varepsilon(A)$ for matrices A (the Roberts sign function). What is special to our case is that our A is hermitian, huge, but sparse. A possible representation is $\varepsilon(x) = \lim_{n \rightarrow \infty} \varepsilon_n(x)$ with

$$\varepsilon_n(x) = \frac{(1+x)^{2n} - (1-x)^{2n}}{(1+x)^{2n} + (1-x)^{2n}} = \frac{x}{n} \sum_{s=1}^n \frac{1}{\cos^2[(s - \frac{1}{2})\frac{\pi}{2n}]x^2 + \sin^2[(s - \frac{1}{2})\frac{\pi}{2n}]} \quad (1)$$

The action of the sum over poles on a given vector can be computed by a slight generalization of the Conjugate Gradient algorithm which uses the same Krylov space for all n inversions, and costs numerically not much more than a single inversion. This is enough to study various properties of D_o , and also of its inverse. Since D_o needs to be inverted, we end up with a two stage nested invertor. I do not know whether the errors in exact arithmetic and, moreover, the errors in real arithmetic, of such a nested algorithm have ever been studied in the applied mathematics literature.

To include the determinant in simulations seems at present too expensive numerically if one must use the nested algorithm. But, there may be a way out, using a continued fraction representation of the approximants $\varepsilon_n(x)$. We want the determinant of $2H_o = \epsilon' + \epsilon_n(H_W)$ in the limit of large n . We add some extra fields, and introduce a new bilinear “action” S_0 :

$$S_0 = \bar{\psi}\gamma_5\psi + \bar{\psi}\bar{A}_1\phi_1 - \bar{\phi}_1A_1\psi + \bar{\phi}_1B_1\phi_1 + \dots + \bar{\phi}_{m-1}\bar{A}_m\phi_m - \bar{\phi}_m\bar{A}_m\phi_{m-1} + \bar{\phi}_mB_m\phi_m \quad (2)$$

Fields with bars are rows, without are columns, and in-between we have square

matrices. We write $S_0 = \bar{\chi}Q\chi$ with $\chi = \begin{pmatrix} \psi \\ \phi_1 \\ \vdots \\ \phi_m \end{pmatrix}$, $\bar{\chi} = (\bar{\psi}, \bar{\phi}_1, \dots, \bar{\phi}_m)$.

Simple manipulations show that if the $A_i, \bar{A}_i, B_i$ are commuting matrices ($\det B_i \neq 0$), we have $\det Q = \prod_{i=1}^m (\det B_i) \det(\epsilon' + R)$ where,

$$R = \frac{A_1 \bar{A}_1}{B_1 + \frac{A_2 \bar{A}_2}{B_2 + \frac{A_3 \bar{A}_3}{B_3 + \dots \frac{\ddots}{B_{m-1} + \frac{A_m \bar{A}_m}{B_m}}}} \quad (3)$$

For the choice of $\varepsilon_n(x)$ in equation (1) we have a representation that goes back to Euler,

$$\varepsilon_n(x) = \frac{2nx}{1 + \frac{(4n^2 - 1)x^2}{3 + \frac{(4n^2 - 4)x^2}{5 + \dots \frac{\ddots}{4n - 3 + \frac{[4n^2 - (2n - 1)^2]x^2}{4n - 1}}}}} \quad (4)$$

Therefore, one can implement the rational approximation by extending the matrix size. One can use other continued fraction representations and other approximants; for example new approximants can be generated by exploiting $\varepsilon(x) = \varepsilon(\lambda x)$ for $\lambda > 0$ or $\varepsilon(x) = \varepsilon(\frac{1}{x})$ for $x \neq 0$. In some of the new continued fractions the B_i matrices may become polynomial in H_W . In this case one needs to compensate for the prefactor $\prod \det(B_i)$ which now carries some dependence on gauge orbits. The compensation is easily done stochastically, using “pseudo-fermions”. Pseudo-fermions are numerical integration variables that carry indices of the same kind as carried by ordinary Grassmannian fermions.

More developments in the area of algorithms as applied to the overlap are expected as the subject is relatively young.

6 Summary

The subject of chirality on the lattice seems to require a wide range of tools from Mathematics. At the one end one has algebraic topology, and at the other numerical analysis. On the way one goes through principal bundles, index theorems, various line bundles, to approximation theory, control theory, orthogonal polynomials, continued fractions, stochastic processes, and numerical linear algebra. Lattice field theory could well use the help of professional mathematicians. I hope more will get interested and involved.

7 Guide to literature

Rather than including detailed references I choose to present a shorter list of mainly review papers. The list is subjective. My recommendation for the prime source to

learn about chiral gauge theories in the continuum are the lectures of L. Alvarez-Gaumé [1]. An important second source I suggest is the review of R. D. Ball [2]. For Berry phase topics I recommend the insightfully annotated collection of papers edited by A. Shapere and F. Wilczek [3]. A recent brief summary of overlap work from the Physics perspective can be found in my contribution to ICHEP98 [4]. A more extended up to date review about overlap work does not exist at the moment; the closest is an older summary paper I wrote with R. Narayanan [5].
